Report:

Crystals of Apical Merozoite Antigen 1 (AMA1) give weak diffraction, precluding the possibility to screen heavy atom dérivatives on a rotating anode source. This has required that the screening be done at a synchrotron beam-line. During the experiment, crystals of AMA1 soaked in three different heavy atom salts were tested : K_2PtCl_6 , K_2PtCl_4 , $K_2Pt(CN)_4$.

Each heavy atom-soaked crystal was first screened by taking a fluorescence spectrum to detect the present of the heavy atom. If present by this test, diffraction data were collected and analysed for the anomalous signal. The $K_2Pt(CN)_4$ and K_2PtCl_6 soakings showed no fluorescence signal and were thus discarded. The K_2PtCl_4 derivative showed an anomalous signal at the peak wavelength (1.071916 Å) and collection was therefore continued at the inflection wavelength (1.072176 Å). A more careful data treatment showed that the anomalous signal dropped rapidly with increasing Bragg angle, reaching noise level at about 5 Å resolution. We have been unable to interpret the Pattersons so far.

Results of data treatment (with HKL) after merging Friedel pairs shows high values of χ^2 to about 6 Å only, suggesting that the Platinum atoms possess a degree of disorder:
